While heart disease presents many challenges because its symptoms are easily masked, it can also be difficult to detect in a patient because of its typically uneven distribution. Numerous imaging techniques can be used to detect such cardiac conditions, including cardiac imaging techniques using X-rays, magnetic resonance (MR) imaging, ultrasonography, and computed tomography (CT). CT is a well-established cardiac imaging modality that provides superb tissue contrast and facilitates generation of accurate reconstructions of the heart, especially coronary artery disease. Some of the techniques are safe and economical, and provide high quality images. However, in clinical practice it is often the case that a combination of tests is needed to identify a patient's condition, or to answer a particular clinical question. Clinical application of the various imaging modalities is, at times, complicated by overlapping or partial volume averaging, large patient size, and patient constraints. For example, coronary CT angiography (CTA) is a medical imaging technique that facilitates visualization of heart anatomy with high accuracy and exquisite resolution. CTA is used extensively for the detection and characterization of coronary artery disease and assessment of treatment options. However, a combination of non-optimal scan techniques or patient related factors can result in coronary artery stenosis not being detected on a CTA scan. This case would be missed because of overlapping and partial volume averaging (PVA). While not limiting the applicability of the inventive
